Multi-channel signals with programmable inter-channel phase

This solution requires a C-size VXI cage, a control card, an E1420A counter and, if more than two E1440As are used, an E1366A switching unit.

Features and benefits

- Slave E1440A frequencies can be a multiple of master frequency.
- Channels can be independently modulated (AM or PM).
- 11-digit frequency resolution.
- Phase accuracy /-2 degree at 20 MHz (even better at lower frequencies due to counter's 200 ps time-interval resolution).
- Output waveforms need not be the same, and are selectable from:
  sine (up to 21 MHz), square or triangle (up to 11 MHz), and ramp (up to 11 kHz). Minimum frequency is 1 uHz.
- 5 ppm stability, if E1440As are daisy-chained. Can be improved by using the counter reference.
- Independent amplitude 1 mVpp to 10 Vpp into 50 ohm. Option 001 provides 4 mVpp to 40 Vpp into 500 ohm.

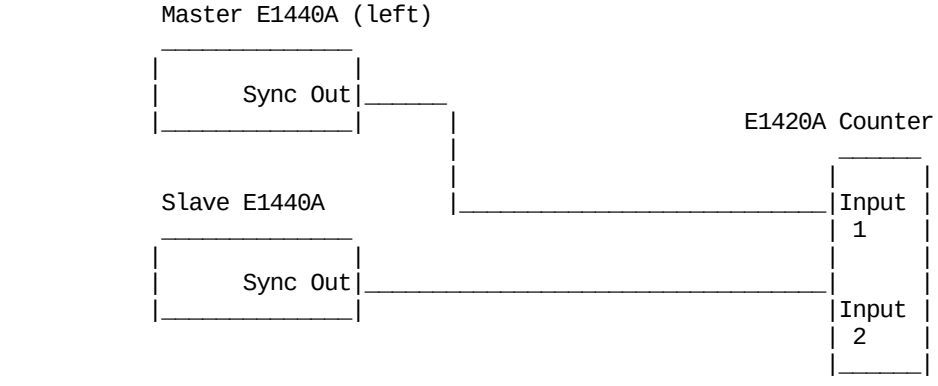
Application example: Navigation Systems

Test of vehicle receivers used in Decca-type location systems requires a number of synthesizers to simulate the signals from a number of fixed transmitters. The frequencies, which are multiples of the master transmitter frequency, must not only be phase-locked, but also of programmable phase so that receiver performance can be verified for any vehicle position.

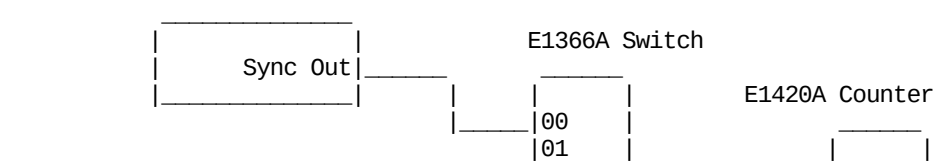
Setting up for the first time

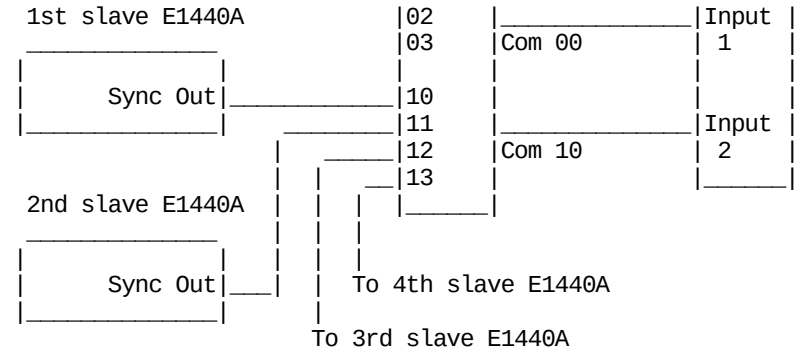
After inserting the modules in the VXI-cage, the front panel connections shown in the following diagram must be made. Additionally, the counter's 10 MHz reference can be "daisy-chained" to all E1440As; this however is not essential, the VXI-internal CLK10 line can be used instead.

a) Two channels



b) Three to five channels





Try to keep the Sync Out path lengths as equal as possible. The same applies to the main outputs. Perform a phase measurement at the device and note any offset needed. With propagation times equalized, the phase accuracy lies in the range /-1 to /- 7 degree depending on waveform and amplitude mix, and frequency.

From here on, correct phase relationship is simply a matter of setting each slave to the required phase. Subsequently, whenever frequency, waveform or amplitude are changed, a phase-cal should be performed. If more than one counter is detected, the one with the lowest slot number will be taken.

Also, the current settings of the counter and switch are stored. This is to allow the counter to be used for other measurements. After the phase calibration, the previous counter settings are automatically recalled.

The calibration is done by the subprogram Sc_calibrate, which first measures the time delay between the positive slopes of the sync signal from the master device (which is used as a reference) and the sync signals from the slaves. It then calculates the phase error between master and slave and adjusts each slave so that all channels are in phase with the master.

After calibration, the program sets the different E1440A's to the desired phase values. Then, as mentioned above, counter and switch are returned to their previous settings.

Automation

UNSUPPORTED programs are attached:

1. PHASECAL: provides a user interface and phase-calibrates automatically.
2. ERRORHANDLING: a utility for use in any application where self-test is to be implemented.

The programs are in HP Basic and stored as ASCII files (use the HP Basic command GET to load the file).

PHASECAL implements phase calibration for up to five HP E1440As. If a daisy-chained reference signal is used instead of VXI line CLK10, change line 109 from:

```
  109  OUTPUT Hpib E1440(I,2);":SOURCE:ROSC:SOURCE CLK10"
       ! CLK10 is ref
```

to:

```
  109  OUTPUT Hpib E1440(I,2);":SOURCE:ROSC:AUTO ON"
       ! Daisy chain ref
```

Initially, the routine detects the cards in the VXI-cage (SUB Sc_getdev) and assigns the E1440A with the lowest slot number as master, the one with the next higher slot number will be slave 1, and so-on. If more than one E1420A counter is detected, the one with the lowest slot number will be taken.

Also, the current settings of the counter and switch are stored.

This is to allow the counter to be used for other measurements.

The calibration is done by the subprogram Sc_calibrate, which first measures the time delay between the positive slopes of the sync signal from the master device (which is used as reference) and the sync signals from the slaves. It then calculates the phase error between master and slave and adjusts each slave so that all channels are in phase with the master.

After calibration, the program sets the different E1440's to the desired phase values, and returns the counter and switch to their previous settings.

```
